## My Solution

I added the centers of the circles to the plot (Figure 1) as well as the radii. Since the two small circles are tangent to the large (blue) circle, their radii are perpendicular to the common tangent lines and so collinear with the radius of the large circle. Furthermore, since the point of intersection C lies on both small circles, it is joined to the respective centers by radii and thus forms two isosceles triangles as shown in the figure.

Since the centers of the two small circles lie on the radius of the large circle all the vertex angles are equal and so all the three triangles formed are similar. This means all the respective sides of the triangles are parallel and so the exposed blue region of the large triangle is a parallelogram. This shows immediately that the sum of the radii of the two smaller circles equals the large circle radius.

Figure 1 My Solution

Figure 2 Converse

Converse. If we assume we have intersecting circles tangent to the large circle at points A and B , then we want to show the line AB passes through the intersection point C if the sum of the radii equals the large radius (Figure 2). Now if the large radius is the sum of the smaller radii (or equivalently, the blue quadrilateral has opposite sides equal), then the blue quadrilateral is a parallelogram. This is proved in Figure 3, since the corresponding triangles are congruent and so

Figure 3 Sides Equal $\Rightarrow$ Parallelogram

Figure 4 Parallelogram $\Rightarrow$ ACB Straight Line
their corresponding angles equal, which implies the opposite sides are parallel. If the blue quadrilateral in Figure 4 is a parallelogram, then $\omega=\omega_{1}=\omega_{2}=\omega_{3}$. This implies all the triangles are similar ( $\therefore \alpha=\sigma=$ angles at A and B of blue triangle) and $180^{\circ}=\alpha+\omega+\sigma=\alpha+\omega_{2}+\sigma$, which means ACB is the straight line AB.

## Quantum Solution

Denote by $\mathrm{O}, \mathrm{O}_{1}, \mathrm{O}_{2}$ the centers of the given circles and by $\mathrm{r}, \mathrm{r}_{1}, \mathrm{r}_{2}$ their respective radii (Figure 5). If segment AB meets circles $\mathrm{O}_{1}$ and $\mathrm{O}_{2}$ at their common point C , then isosceles triangles $\mathrm{OAB}, \mathrm{O}_{1} \mathrm{AC}, \mathrm{O}_{2} \mathrm{BC}$ are similar to one another (triangles OAB and $\mathrm{O}_{1} \mathrm{AC}$, say, have a common angle at vertex A). So the opposite sides of quadrilateral $\mathrm{OO}_{1} \mathrm{CO}_{2}$ are parallel and, therefore, congruent (by a property of the parallelogram). It follows that

$$
\mathrm{r}=\mathrm{OA}=\mathrm{O}_{1}+\mathrm{O}_{1} \mathrm{~A}=\mathrm{O}_{2} \mathrm{C}+\mathrm{O}_{1} \mathrm{~A}=\mathrm{r}_{1}+\mathrm{r}_{2}
$$

The converse is also true: if $r=r_{1}+r_{2}$, then segment AB passes through one of the common points of the smaller circles. To prove it, construct the parallelogram $\mathrm{OO}_{1}{ }^{\prime} \mathrm{CO}_{2}{ }^{\prime}$,, whose vertices $\mathrm{C}^{\prime}$ and $\mathrm{O}_{2}{ }^{\prime}$ lie on segments AB and OB , respectively (clearly this can always be done in a unique

Figure 5 Quantum Solution way). Triangles $\mathrm{O}_{1} \mathrm{AC}^{\prime}$ and $\mathrm{O}_{2} \mathrm{C}^{\prime} \mathrm{B}$ are similar to isosceles triangle OAB , so

$$
\mathrm{O}_{1} \mathrm{C}^{\prime}=\mathrm{O}_{1} \mathrm{~A}=\mathrm{r},
$$

which means that $\mathrm{C}^{\prime}$ lies on circle $\mathrm{O}_{2}$, and

$$
\mathrm{O}_{2}^{\prime} \mathrm{B}=\mathrm{O}_{2}^{\prime} \mathrm{C}^{\prime}=\mathrm{OO}_{1}=\mathrm{OA}-\mathrm{O}_{1} \mathrm{~A}=\mathrm{r}-\mathrm{r}_{1}=\mathrm{r}_{2}
$$

which means that $\mathrm{O}_{2}{ }^{\prime}=\mathrm{O}_{2}$ and that $\mathrm{C}^{\prime}$ lies on circle $\mathrm{O}_{2}$, which is what we had to prove. (V. Dubrovsky)
